ABSTRACT

Background and Objective: Inflammatory pseudotumor is a lesion composed of proliferating spindle cells with mixed inflammatory infiltrates. Some authors have proposed the name inflammatory myofibroblastic tumor as a proper descriptive term rather than the vague inflammatory pseudotumor. The aim of this study was to verify the myofibroblastic origin of spindle cells in idiopathic orbital inflammatory pseudotumor by immunohistochemical staining.

Materials and Methods: We reviewed a series of 32 inflammatory pseudotumors arising in orbit for expression of smooth muscle actin, vimentin, desmin and anaplastic lymphoma kinase using immunohistochemical staining.

Results: There were 21 females and 11 males aged 3 to 64 years with a mean age of 31.

Immunohistochemically, spindle cells of 51.75%, 79.3%, and 17.2% of lesions expressed smooth muscle actin (15/29), vimentin (23/29) and desmin (5/29). All lesions (32/32) were negative for anaplastic lymphoma kinase.

Conclusion: In this study, reactivity for smooth muscle actin in spindle cells can be demonstrated as myofibroblastic differentiation. The absence of anaplastic lymphoma expression in all cases of orbital inflammatory pseudotumor in this study strongly suggests that these lesions, albeit histologically similar, are biologically distinct from their soft tissue counterparts or those inflammatory myofibroblastic tumor that negative for anaplastic lymphoma immunoreactivity may be characterized by one or more chromosomal aberration involving regions other than 2p23 is as yet unknown.

Key words: Inflammatory pseudotumor, Orbit, ALK kinase
Introduction

Idiopathic inflammatory pseudotumor (IPT) of the orbit or eye is a rare, benign and self-limited disorder (1-4). These tumors most commonly arise in the lungs and abdomen, but they have been reported in virtually all anatomic subsets of the body in patients of all ages (5). In the head and neck, the orbit is the most common site of occurrence (5). Its pathogenesis is unknown.

The diagnostic entity “inflammatory pseudotumor” has undergone something of a revolution in recent years. What was once a heterogeneous group of poorly defined entities has been refined, and it presently encompasses several distinct biologic processes including both reactive condition as well as neoplasm (6-9). Some authors have proposed the name “inflammatory myofibroblastic tumor” as a proper descriptive term for this tumor, rather than the vague “inflammatory pseudotumor. Inflammatory myofibroblastic tumor (IMT) is a lesion composed of proliferating myofibroblastic spindle cells with mixed inflammatory infiltrates of lymphocytes, plasmacells, eosinophils and histiocytes (10).

Histopathologic discrimination of these lesions may require careful attention not only to the histopathologic findings but also to clinical course and to additional diagnostic tools, particularly immunocytochemistry. The neoplastic nature of IMT was confirmed by proving the presence of clonal abnormalities in the short arm of chromosome2 (2;3;6-8) involving the anaplastic lymphoma kinase (ALK) gene. Resultant ALK protein over-expression in myofibroblastic cells was found out in 35% to 60% of IMT cases, suggesting neoplastic nature of these tumors rather than a reactive or reparative process (6-8). However, the concept of the same lesions in orbit was not changed and was still referred to as “inflammatory pseudotumor” (IPT) but in a few case reports used term “inflammatory myofibroblastic pseudotumor” when myofibroblasts were rich in the mass. We consider that they are the same lesion that occurs in the other soft tissue and suggest that they be referred to in unison as IMT.

To verify the histopathology and immunohistochemistry for myofibroblastic differentiation and ALK expression of orbital IPT, we analyzed clinicopathologic features and performed SMA, vimentin, desmin and ALK immunohistochemistry on 32 cases of orbital IPT.

Materials and Methods

Thirty two cases of orbital inflammatory pseudotumor were selected from the histopathology files of the Department of Pathology at the Farabi hospital between 1991 and 2007. Clinical information (age and sex of the patient, site and side of the lesion) was obtained from the pathology report.

Hematoxylin and Eosin-stained slides were reviewed in all cases. All cases met the established light microscopic histopathologic criteria for orbital inflammatory pseudotumor (11). Formalin-fixed, paraffin-embedded sections were available in all cases. Immunohistochemical staining was performed using a conventional labeled stereptavidin-biotin method according to the manufacturer’s protocol. Briefly, 4 μm tissue sections were placed on silanecoated slides, deparaffinized, and rehydrated with graded ethanol and phosphate-buffered saline. After antigen retrieval by microwaves blocking endogenous peroxidase, goat serum to prevent nonspecific reaction and primary antibodies were applied sequentially. The primary antibodies (Table 1) used were as follows: SMA (n = 29; DAKO, dilution 1:100), vimentin (n = 29; DAKO, dilution 1:100), desmin (n = 29; DAKO, dilution 1:100) and ALK-1 protein (n = 32; DAKO, dilution 1:250). These slides were incubated in biotinylated goat anti-mouse immunoglobulin and then in a solution of stereptavidin-biotin complex. Immunoreactivity was visualized using 3,3-diaminodenzidine (DAB).

Reaction was interpreted as positive if a distinct precipitate was present in cytoplasm of the spindle cells. The positive control for ALK-1 was an anaplastic large cell lymphoma, which showed a diffuse cytoplasmic positivity. Positive reaction of α-SMA with or without vimentin or desmin was considered as myofibroblastic differentiation.

IRANIAN JOURNAL OF PATHOLOGY
Results

Clinical features
The patients’ mean age was 31 years (ranging from 3 to 64 years) and females were affected more often than males (1.9/1). Tumor side varied and included the right (n = 15, 46.9%) and left (n = 17, 53.1%). The most common presentation was proptosis followed by pain and swelling.

Gross and microscopic findings
The lesions were unilateral (n = 30) or bilateral (n = 2) ranging in size from 0.3 to 4 cm (mean 1.37 cm) and having gray-white to creamy-brown color.

Microscopically, all cases were composed of spindle cells, a variable fibrocollagenous stroma, and inflammatory cells component made up lymphocytes, plasmacells, histiocytes, neutrophils and eosinophils. The proportion of each of these elements varied between cases, as well as within cases. Other histopathological findings including perivascular lymphocytic infiltration, fat necrosis, lymphoid follicle formation myositis and dacryoadenitis variably were also seen in some cases. The spindle cells had a long and eosinophils cytoplasm without cross-striation (Fig. 1). Mitosis and coagulative necrosis was not present. Type of lesions is summarized in Table 2.

Immunohistochemical findings
The spindle cells were immunoreactive for alpha smooth muscle actin (SMA) in 15 out of 29 cases (Fig. 2) and vimentin in 23 out of 29 cases, 51.7% and 79.3%, respectively. Thirty two out of 32 cases studied were negative for the ALK-1 protein (Table 3).

Fig.1: (A & B) inflammatory pseudotumor of orbit. The lesion composed of spindle cells admixed with inflammatory infiltrated cells (×100 & ×400).

Fig. 2. Spindle immunoreactivity for SMA (smooth muscle actin) (Avidin-biotin peroxidase; ×100 & ×400). Note the follicle formation of inflammatory cells.

Discussion

Despite many studies, the nature of IPT has remained a curious lesion. It was originally described in the lung and called plasmacell granuloma (12). The term inflammatory myofibroblastic tumor commonly referred to as inflammatory pseudotumor in the earlier literature (13) and implies for myofibroblastic differentiation, which is supported by immunohistochemical and ultrastructural data. IMT is a neoplastic process that can arise in many sites within the head and neck including orbit (14-16). The histological features of this tumor vary slightly from site to site, which may at least in part, be related to the differences in the phase of the lesion’s development at the time the lesion becomes symptomatic or detectable. The histopathologic examination is essential to the diagnosis of IMT. Microscopically, IMTs are composed of proliferating spindle cells, a variably
prominent collagenous stroma and a background of inflammatory cells consists mainly of lymphocytes and plasma cells. Immunohistochemical staining is useful in confirmation of the myofibroblastic phenotype (17-20).

Our immunohistochemical findings for myofibroblastic differentiation are similar to other authors (8;21-29). Immunohistochemically, most of the spindle cells showed evidence of myofibroblastic differentiation, as 15/29 cases stained for smooth muscle actin and 23 out of 29 cases stained for desmin, in contrast to the findings of Facchetti et al that most spindle cells were positive for vimentin and macrophages-associated markers (30) and by Selves et al that is derived from follicular dendritic reticulum cells (FDRC) (31). Some IMTs may exhibit aggressive local behavior and rarely metastasis (32) and some of them do not respond to conventional treatments (corticosteroids) which point to the possibility that at least some subsets of IMTs are in fact true neoplasm (6;7).

Recent cytogenetic and molecular studies have identified abnormalities of chromosome 2p23 (short arm of chromosome 2 at the region p21-p23, the site of the ALK gene that codes for a tyrosin kinase receptor) (7;33-36). In IMTs immunohistochemistry for ALK-1, P80 is useful as an indicator of 2p23 abnormality and the sensitivity of both antibodies are known to be comparable (8). ALK immunoreactivity has been reported in 36% to 60% of IMT (7;8;14;26;29;33;36;37). ALK-1 reactivity lends support to the diagnosis of IMT and its neoplastic feature. Thirty two cases of orbital IPT were obtained from our files. Immunohistochemistry for ALK receptor kinase expression did not detect ALK kinase expression (0 out of 32). This finding is in sharp contrast to that of Lawrence et al (34) who showed strong ALK kinase expression by immunohistochemistry in 7 out of 11 cases of soft tissue IMT; Coffin et al (7) who reported 12 out of 45 cases of IMT positive for ALK kinase and other studies (7;8;14;26;29;33;36;37). Further support for the absence of ALK expression in some IPTs comes from a study by Neuhauser et al who found no ALK expression in 10 out of 10 cases of splenic IPT (23), Jeffery et al that none of their 13 cases of splenic and lymph node IPT showed ALK expression (38) and other studies (18). Several studies have proposed a role for EBV (23;39) and HHV8 (39;40). One of two case reports of orbital IMT shows ALK expression (28) and another study shows no immunoreactivity for ALK (18). So, the absence of ALK expression in all cases of orbital IPT in this study and most others orbital IMT studies strongly suggests that these lesions, albeit histologically similar, are biologically distinct from their soft tissue and should be considered histopathologic and clinical information and those IMTs that are negative for ALK immunoreactivity may be characterized by one or more chromosomal aberration involving regions other than 2p23 is as yet unknown counterparts.

**Conclusion**

Although ALK immunoreactivity clearly dose not distinguish between a reactive and a neoplastic process, it is possible that FISH analysis for ALK gene alternation might be useful in distinguishing those lesions that are truly neoplastic from those that are reactive.
